Lecture 1

Background for Computability

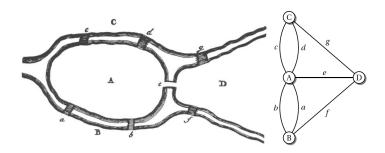

MSc in Physics Engineering - Quantum Computation, L. S. Barbosa, 2021-22

Summary

- (1) An invitation to computability and computational complexity: Eulerian and Hamiltonian paths.
- (2) Computation and mathematics: Babbage's calculators and Hilbert's Entscheidungsproblem
- (3) A brief background tour: Sets, functions, relations.

1 Computability and complexity: Eulerian and Hamiltonian paths

Euler's problem (1736): crossing the bridges of Königsberg

A walk through a graph that crosses each edge once.

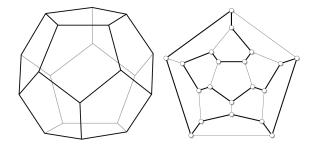

- Exhaustive search: computation time exponential on the number of bridges.
 - As far as the problem of the seven bridges of Knigsberg is concerned, it can be solved by making an exhaustive list of possible routes, and then finding whether or not any route satisfies the conditions of the problem. Because of the number of possibilities, this method of solutions would be too difficult and laborious, and in other problems with more bridges, it would be impossible.
- **The theorem**: computation time scales linearly, ... and offers a useful explanation: The existence of a path was shown equivalent to a much simpler property.
 - A connected graph contains an Eulerian path if and only if every vertex, with the exception of the vertices where the path starts and ends, has even degree.

Exercise: Can you find a rigorous proof of Euler's theorem? Based on the insight you may take from the proof, can you design a simple algorithm that constructs an Eulerian path in a given graph?

Hamilton's problem (1859): walk around the edges of a dodecahedron

Finding an Hamiltonian path, which visits each vertex once, is not known to be reductble to an easier problem. Thus, the best possible algorithm scales exponentially on the number n of nodes, requiring an execution time proportional to 2^{kn} , for k a constant.

Exercise: Does the actual value of k actually matter?

While **finding** a Hamiltonian path seems to be hard, **checking** whether a given path is Hamiltonian is easy: simply follow the path vertex by vertex, and check that it visits each vertex once. This turns out to be an important observation for the future.

2 Computation and mathematics

Let us forget about how an algorithm scales, and ask instead if, for any problem, there is an algorithm that solves it given a finite, but arbitrary, amount of time.

Basic ingredients of computation

• Processor: a programmable device that can carry out any given algorithm.

Charles Babbage: I wish to God that these calculations had been executed by steam! (1821)

cf the Difference engine and Analytical engine:

The Analytical Engine does not occupy common ground with mere calculating machines. In enabling mechanism to combine together general symbols in successions of unlimited variety and extent, a uniting link is established between the operations of matter and the abstract mental processes of the most abstract branch of mathematical science... (Ada, Countess of Lovelace)

• **Algorithm**: specification, in a precise language, of a way to carry out some calculation or solve a problem.

Algorithms as well-defined mathematical objects, were not object of specific study until the 20th century.

David Hilbert's 10th problem:

Specify a procedurewhich, in a finite number of operations, enables one to determine whether or not a given Diophantine equation with an arbitrary number of variables has an integer solution. (1900)

More generally,

The Entscheidungsproblem is solved if one knows a procedure that allows one to decide the validity of a given logical expression by a finite number of operations (1928)

For example, give an algorithm to express, for example, Fermat's last theorem and determine, in a finite amount of time, whether it holds or not:

$$\neg \exists_{x,y,z,\in\mathbb{N}-\{0\},n\geq 3}. \ x^n+y^n=z^n$$

If the answer to this question was positive, this would pave the way to the *mechanization* of mathematics.

Developments in both sides actually **converged**:

- The quest for an *axiomatic foundation for mathematics*, ie. the attempt to reduce all of mathematics to set theory and logic, creating a formal system powerful enough to prove all the mathematical facts, became problematic and lead to paradoxes. But at the turn of the century, several paradoxes: cf the Russell's paradox *the set of sets that are not elements of themselves is not a well-defined mathematical object*. Later (1936) Godel proved that no formal system can provide a complete foundation for mathematics, thus putting an end to Hilbert's programme.
- The quest for a universal processor and suitable notion of program lead to a number of equivalent notions of a universal processor (Turing machine, λ-calculus, recursive functions) and a fundamental conjecture the *Church-Turing thesis* that these notions capture anything that could be reasonably called a computation. A. Turing (also in 1936) formulated a problem the *Halting Problem* (does a given program ever terminate?) and showed it undecidable.
- The techniques used for understanding Russell's paradox and the Halting problem are similar: it is the the self-referential nature of computation which leads to both undecidable problems and unprovable truths (as we will explore in the next lecture).

For the moment, let us revisit a few notions and techniques of set theory.

3 Sets, functions and relations

(recall your HASKELL experience)

- Function $f : A \longrightarrow B$. Composition.
- Notation A^B to represent the space of functions from B to A.
- Injective, surjective and bijective functions.
- Powerset $(\mathcal{P}(A) \text{ or } 2^A)$.
- Russell's paradox.
- Binary relations; $2^{A \times B} \cong 2^{A^B}$.
- Equivalence relations. Orders.

Finite and infinite sets

- equicardinality vs isomorphism.
- finite vs infinite.

• countable vs uncountable:

A set A is *countable* iff there is an injective function $f : A \longrightarrow N$. It is *infinite countable* if f is a bijection.

Ranking cardinality

$$|A| \le |B|$$
 iff there is an injection $f : A \longrightarrow B$

Relation \leq above is a total order. Note that proving antisymmetry (i.e. the Cantor-Bernstein-Schroeder theorem) and totality (which requires the axiom of choice) is extremely hard.

Some applications

Theorem

 \mathbb{N} and \mathbb{Z} have the same cardinal

Proof (hint).

Consider $h: \mathbb{Z} \longrightarrow \mathbb{N}$ defined as follows and show it is a bijection:

$$h(x) = \begin{cases} 2x & \Leftarrow x \ge 0 \\ -2x + 1 & \Leftarrow \text{otherwise} \end{cases}$$

Theorem

 \mathbb{N} and $\mathbb{N} \times \mathbb{N}$ have the same cardinal

Look for a bijection between \mathbb{N} and $\mathbb{N} \times \mathbb{N}$. Let's see some (of several) possibilities:

Proof (1).

Enumerate all pairs of numbers which sum $0, 1, 2, \cdots$:

(0,0)

(0,1) (1,0)

(0,2) (1,1) (2,0)

(0,3) (1,2) (2,1) (3,0) ...

For every sum n there are only finitely many, actually n + 1 pais (i, j) that sum n. I.e. for every number n, one gets all the pairs which sum n. On the other hand, since every pair of numbers

(i, j) has a finite sum it will appear somewhere on this list. This defines a bijection

$$(0,0) \mapsto 0$$

$$(0,1) \mapsto 1$$

$$(1,0) \mapsto 2$$

$$(0,2) \mapsto 3$$

$$(1,1) \mapsto 4$$

.

Proof (2).

Consider the following correspondence:

$$n \mapsto (i,j)$$

such that n = 2i + j (i.e. basically factoring number n in its odd and even parts). Clearly the pair (i, j) is unique, thus establishing a bijection

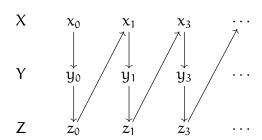

$$f: \mathbb{N} \longrightarrow \mathbb{N} \times \mathbb{N}_{odd}$$

Remains to prove that $\mathbb{N} \cong \mathbb{N}_{odd}$.

Theorem

The union of a finite number of countably infinite sets is countably infinite.

Proof (hint).

Theorem

 $|\mathbb{N}| < |\mathbb{R}|$

Proof. (1)

To show that $|\mathbb{N}| \leq |\mathbb{R}|$ is trivial: function h(n) = n is injective.

The difficult part is to prove that $\mathbb{N} \neq \mathbb{R}$. Let us prove an even stronger statement: that there is no surjection from \mathbb{N} to [0,1[. Consider an arbitrary function $h:\mathbb{N}\longrightarrow [0,1[$ with which one may enumerate an infinite sequence of real numbers

$$r_0, r_1, r_2, \cdots$$

making $r_i = h(i)$.

To show that h in not surjective, we have to find a real x such that $r_n \neq x$ for all $n \in \mathbb{N}$. Let us build x as an infinite dizime

$$0.x[0]x[1]x[2]\cdots$$

such that

$$x[i] = \begin{cases} 1 \Leftarrow r_i[i] = 0 \\ 0 \Leftarrow \text{ otherwise} \end{cases}$$

Observe that any real h(n) differs from number x exactly in position n, and conclude that x does not belong to the image of h.

Proof. (2)

If both sets were the same size, it would be possible to put them in one-to-one correspondence. In other words, there would be a way to list all subsets as S_0, S_1, \cdots and so on, such that for every $S \subseteq \mathbb{N}$, then $S = S_i$, for some $i \in \mathbb{N}$.

In a table list the elements of S

Now, take the diagonal of this table, and flip all its bits. This gives us a new set D. Since $i \in D$ iff $i \notin S_i$, then $D \neq S_i$, for all i. Therefore, table D is not complete. Any correspondence between $\mathbb N$ and $2^{\mathbb N}$ leaves at least one subset out.

These are examples of a popular proof principle: diagonalization.

The argument can be generalised:

Exercise (Cantor Theorem)

Generalise the previous proof to show that, for any set X, $|X| < |2^X|$.

Proof (Cantor Theorem).

Function

$$\eta: \chi \longrightarrow \{\chi\}$$

is trivially injective. However there is no surjection $h: X \longrightarrow 2^X$.

To argue by contradiction, suppose such a function h exists and consider a set

$$W = \{x \in X \mid x \notin h(x)\}$$

If h is indeed surjective it must exist an element $w \in X$ such that h(w) = W and w may or may not belong to h(w).

These two cases are as follows as both lead to a contradiction:

- $w \in h(w)$ but then $w \notin W$,
- $w \notin h(w)$ but then $w \in W$

which invalidates our assumption that h is a surjection.

NOTE: problems and algorithms. This theorem sheds light on the limits of computability: there are more problems that we might want to solve than there are programs to solve them, even though both are infinite.

To see this, restrict your attention to one type of problem: deciding whether a string has some property (e.g. having even length, being a palindrome, or a legal Haskell program). A property can be identified with the set of strings that happen to share it. Clearly, the number of possible programs is no bigger than the number of strings, while the number of sets of strings is strictly greater.

This shows the existence of unsolvable problems, i.e. problems that can be formulated but not possibly solved.

Another important principle is the following:

Theorem: the pigeonhole principle

Let m objects be distributed into n containers. If m > n, then some container contains at least two objects

Or

If f is a function from a set S to a smaller set R, then there must be some pair x, y such that f(x) = f(y).

I.e. if S pigeons nest in a smaller set of nests, at least one pair of pigeons must nest together.

Proof.

By contrapositive: let us show that if every container contains at most one object, then $m \le n$.

If c_i is the number of objects in container i, then

$$m = \sum_{i=1}^{n} c_i$$

but, every container contains at most one object, we get

$$m = \sum_{i=1}^{n} c_i \le \sum_{i=1}^{n} 1 = n$$

Applications: Given a large enough number of objects with a bounded number of properties, eventually at least two of them will share a property.

Ex. 1

Suppose that every point in the real plane is coloured either red or blue. Then for any distance d > 0, there are two points exactly distance d from one another that are the same color.

Ex. 2

Similarly, there are at least two Portuguese citizens with exactly the same number of individual hair in their heads.

Ex. 3

For any natural number n, there is a nonzero multiple of n whose digits are all 0s and 1s.

Remark on no constructive proofs.

The proofs applying the pigeonhole proofs are non-constructive, i.e. although they prove the existence of something, they fail to provide an explicit example that proves the theorem. Constructive proofs are the ones more suitable for Computer Science (why?).

This may be illustrated with two proofs of the following result:

Theorem: There exist irrational numbers x and y for which x^y is rational

Proof (non-constructive).

Let $x = \sqrt{2}^{\sqrt{2}}$ and $y = \sqrt{2}$. Number y is irrational, but we do not know whether x is rational or irrational. Thus,

• If x is irrational, then we have an irrational number to an irrational power that is rational:

$$x^{y} = (\sqrt{2}^{\sqrt{2}})^{\sqrt{2}} = \sqrt{2}^{(\sqrt{2} \times \sqrt{2})} = \sqrt{2}^{2} = 2$$

• If x is rational, then

$$y^y = x$$

is rational. Either way, we conclude that there is an example of a power of irrational numbers that is rational.
